September 2013

1   Introduction

Earnings questions have been asked in South Africa's national surveys annually since 1994. A key question for labour economists has been to track and explain the evolution of earnings over this post-apartheid period. Unfortunately, however, the measurement instrument has changed in ways that make it tricky to simply take the raw figures and compare them even if one restricts the attention to the October Household Surveys and the various Labour Force Surveys. In this paper we analyse some of the changes and indicate where corrections are needed. We implement many of these changes in the second release of PALMS, the Post-Apartheid Labour Market Series (Kerr, Lam and Wittenberg 2013).

The structure of the paper is as follows. In section 2 we review studies done on the earnings variables in the national surveys from Statistics South Africa, particularly those that comment on the comparability of the variables over time. In Section 3 we pay attention in more detail to the evolution of the measurement instrument. We then turn to an analysis of the actual responses in section 4 with a view to pinpointing where the underlying measurements may have changed. The following sections deal with ways of handling bracket information and missing data respectively . In section 8 we look at the impact of these data quality adjustments on the estimation of average real earnings over time.

2   Literature

Several papers have looked at the post-Apartheid wage series and commented on the comparability (or otherwise) of the earnings information. Casale (2004) remarked on a precipitous decline in real earnings over the period 1995 to 2001. She notes that better enumeration of low wage work may explain some of the decline, but argues that

> the fall in informal self-employment earnings between 1995 and 2001 is unlikely to
> be the result of improved data collection alone, as more and more people crowding

into already low income-generating informal activities would be expected to depress average earnings even further. (Casale 2004, p.264)

The most comprehensive review to date is by Burger and Yu (2007). They argue that the bulk of the decline in earnings is driven by the discontinuity between the October Household Surveys (OHSs) and the Labour Force Surveys (LFSs). They also note that outliers contaminate the series, a problem which they argue is particularly noticeable in the September 2000 LFS. In other regards the LFS series is less prone to extreme incomes. On the other hand they suggest that people earning more than R1 million a year affect average earnings in all years prior to 2000, and argue that

> This is due mainly to changes in the earnings intervals that individuals were allowed to specify without revealing their exact incomes, which permitted all workers in 1995 and the self-employed in 1996 to 1998 to answer in higher income brackets than were available to respondents in the subsequent years. (Burger and Yu 2007, p.6)

This comment indicates that the issue of bracket responses and how they are utilised in the calculation of "average earnings" is of some importance. Neither Casale nor Burger and Yu discuss how this was achieved. One of the more popular procedures for doing so is by placing the bracket respondents at the midpoint of the interval. In the case of the open category the typical procedure is to take some multiple of the lower bracket boundary. Both von Fintel (2007, p.297) and Yu (2011, p.14) suggest that the factor that should be used is 1.1. This seems remarkably conservative. Simkins (personal communication) by contrast suggests that the value of the lower bracket boundary should be doubled. The reason is that the distribution in the upper tail is approximately Pareto with a coefficient of approximately two. Other work (Wittenberg 2013) estimates the Pareto parameter at around 1.85, suggesting that the factor should be around 2.17, i.e. Simkins's rule of thumb has much better grounding in the data. We will return to the issue of bracket responses and how to deal with them later. At present it suffices to note that how this information is incorporated into the analysis is of considerable importance and that this is not always appropriately documented in the analyses that have been conducted.

Another strand of the literature deals with changes in the instrument. Daniels (2013) investigates changes in the earnings question addressed to employees in the 1997-1999 October Household Surveys and the 2000-2003 Labour Force Surveys. He focuses particularly on how missing information is dealt with. Unfortunately some rather large changes in the instrument precede this period (as shown below) and one of the biggest breaks between the October Household Surveys (OHSs) and the Labour Force Survey (LFSs) is the collapse of two separate questions (in the OHSs) to just one question in the LFSs.

Yu (2007) provides a detailed discussion of many variables measured in both the OHSs and LFSs, including earnings. He shows that there was an increase in the reporting of zero incomes and unspecified responses with the change to the LFSs. Indeed the February 2000 survey seems particularly anomalous with regard to both (Yu 2007, Table 24, p.27). In a companion piece (Yu 2009) he discusses the relationship between the LFSs and the Quarterly Labour Force Surveys (QLFSs) introduced in 2008. He does not consider the question of earnings, because in the period he reviewed there was no earnings information available for the QLFSs.

Yet other work has considered the evolution of sampling practice and the resultant breaks in the series. Kerr and Wittenberg (2013) argue that the change in survey practice between the 1998 October Household Survey and the 1999 OHS led to better enumeration of backyard shacks, which led to a marked increase in the number of backyard shack dwellers interviewed. As a result some of the early surveys might present a too rosy picture of conditions in South Africa. Indeed 1995, which has been used as the "anchor" for many post-Apartheid analyses (Branson

2

Table 1: Respondents giving Gross Income or Take-home pay in OHS 1994

Gross/take-home pay? Q3.14	Freq.	Percent
1=Total salary before deductions	10517	34.87
2=Take-home pay	19646	65.13
Total	30163	100

Note: Unweighted counts and percentages of individuals giving nonmissing information

and Wittenberg 2007, Appendix 1, pp.322ff.) appears anomalous on many measures (Branson and Wittenberg 2007, Wittenberg forthcoming). While cognisant of these problems we will not be able to address all of them as fully as they deserve. Indeed the question as to how to deal with changes in the sample coverage is still subject to research.

3 Changes in the Instrument

There are several changes in the survey instrument. As noted above, perhaps the most far-reaching of these is the change from 2 questions in the OHSs to one in the LFS, since this coincides with the shift to more extensive probing of informal sector activity. As Burger and Yu (2007) suggest, this break leads to a downward shift in measured wages. However, there are also some really big changes in the measurement instrument in the first three years, which create additional issues when trying to assess conditions at the point at which Apartheid was being dismantled. Our discussion therefore breaks the series into four parts: the early OHSs 1994-1996, the later OHSs 1997-1999, the LFSs 2000-2007 and the QLFSs since 2008

3.1 The early October Household Surveys: 1994-1996

This period seems to have been a period of experimentation - where the "earnings question" eventually converged on an agreed on template. Each of these surveys has its own idiosyncracies. 1994 allowed both "gross" and "net" wages to be reported, whereas thereafter the employee earnings question was clearly about gross income. In both 1994 and 1995 respondents are allowed to choose an earnings category and are asked **subsequently** whether this income was earned daily, weekly, monthly or annually. The upshot is that there are effectively four **sets** of earnings categories – one for each reporting period. By 1996 this practice had changed and the conversion between reporting periods was done on the instrument, resulting in only one set of categories. 1996 was idiosyncratic in other ways, though, since it was run in conjunction with the Post-enumeration survey for the census. This meant that not only was the sampling done differently, but a smaller sample was extracted and a much simpler instrument used. The upshot was that only categorical income information was collected.

3.1.1 1994

The earnings question asked of employees is shown in Figure 8. The first point to note is that this earnings question does not stipulate whether gross or net income should be reported. Instead a subsequent question (3.14) asks whether the reported number is before or after deductions. Table 1 shows the "raw" responses from that survey. Interestingly around two-thirds of respondents gave a "net" figure when not prompted.

By 1995 (see Figure 10) this level of ambiguity was removed and since then the earnings question has been explicitly about earnings before deductions. What might the impact of this
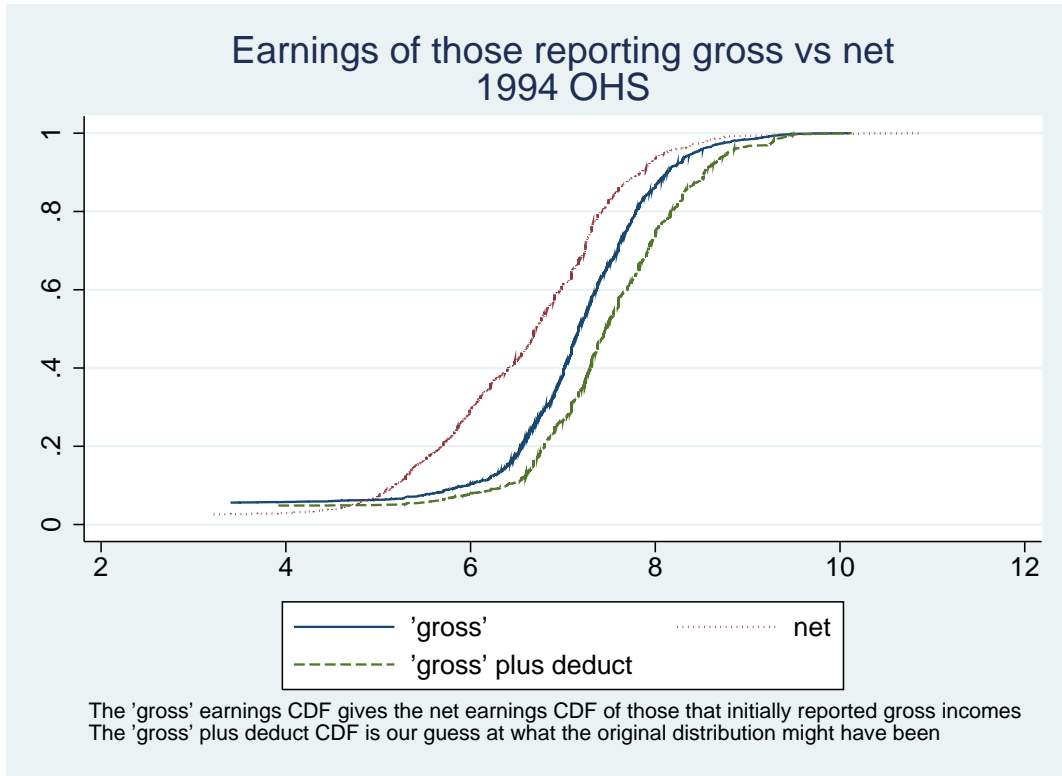

Figure 1: The distribution of earnings of individuals giving gross earnings versus those giving "take-home pay" in the 1994 OHS.

be? If we had the original responses from the 1994 OHS it would be possible to answer this question. Unfortunately (as discussed in more detail below) the responses have been heavily processed and only a "net income per month (calc)" variable released. Nevertheless we see in Figure 1 that if we graph the distributions by whether or not the person initially gave gross figures, we get very dissimilar CDFs, with strong evidence that those giving "gross" figures reported considerably higher incomes. At face value this suggests that individuals who found it easy to recall their gross income tend to be disproportionately higher earners. This may be a reflection of the fact that formal sector workers with formal pay slips may have better knowledge of their gross income. It also suggests that they would have a higher propensity to report gross incomes. The difference between the CDFs is sufficiently marked that one might presume that there was a processing error, i.e. that the reported net income (labelled 'gross' in the figure) was actually not an after-deductions figure. Indeed if we deduct the reported expenses from the "net" figures of those initially reporting gross figures we get a CDF very similar to those giving "take-home pay", at least at higher earnings. At lower earnings, however, the "net" figures really seem post-deductions, because subtracting expenses from these figures results in implausibly low earnings. Indeed for 10% of the figures the deductions would exceed the salary.

This all raises questions not only about the initial responses but precisely what sort of post-data collection processing occurred. Unfortunately with the current data we cannot reconstruct precisely what the information means. One additional problem is that the "deductions" question

Table 2: Responses to the Income bracket question in OHS 1995 by earnings period

Total salary at main job	Number of Responses				Percentage of Valid Responses			
	Earnings period				Earnings period			
	Day	Week	Month	Year	Day	Week	Month	Year
1. No income		3	29	1		0.6%	0.6%	0.2%
2. R1 - R999	26	491	1321	2	100.0%	97.2%	25.5%	0.4%
3. R1 000 - R1 249		5	546	1		1.0%	10.5%	0.2%
4. R1 250 - R1 499		2	389	1		0.4%	7.5%	0.2%
5. R1 500 - R1 999		3	547	4		0.6%	10.6%	0.7%
6. R2 000 - R2 499		1	443	5		0.2%	8.5%	0.9%
7. R2 500 - R2 999			478				9.2%	
8. R3 000 - R3 999			546				10.5%	
9. R4 000 - R5 999			538	5			10.4%	0.9%
10. R6 000 - R7 999			192	14			3.7%	2.6%
11. R8 000 - R9 999			70	7			1.4%	1.3%
R10 000 and above			84	506			1.6%	92.7%
Total	26	505	5183	546	100.0%	100.0%	100.0%	100.0%

Note: Unweighted counts and percentages of individuals giving nonmissing responses

in 1994 (question 3.14) is aked only of individuals reporting a "gross" figure. It is therefore not possible to create a gross earnings variable for all respondents in 1994.

To investigate the relationship between deductions and earnings, we ran a regression (of log deductions on log earnings). The estimates for 1994 suggest that deductions increased from around 6% at low incomes to around 38% at incomes of R10 000. In 1995 the deductions question was asked of everyone and it is therefore easier to make sense of the information. Rerumnning the regressions we found a similar relationship with a similar level of fit (R^2 of around .66), with deductions increasing from negligible levels to around 40% with incomes of R10 000.

3.1.2 1995

While the earnings question as a whole is better in 1995, the earnings brackets used in that year are extraordinary, to say the least (see Figure 10 and Figure 11). The lowest category with positive earnings extends in both cases from R1 to R999. Given the shape of South Africa's earnings distribution the bulk of African monthly earnings would be in this category. Even more remarkably, since the earnings period was asked after the bracket question, daily paid workers that ticked this category could be earning anywhere between R1 and R22 000 per month (assuming 22 working days per month). As shown in Table 2 there are over 500 respondents in this category who were paid either daily or weekly.

3.1.3 1996

We noted above that the 1996 survey collected information **only** in brackets. Furthermore the bracket questions are now set up so that the conversion between different reporting periods is made explicitly in the question (see Figures 12 and 13) so that there is only one set of brackets. Moreover the earnings brackets for employees become the standard for all the later OHSs and LFSs. One additional point worth noting is that unlike in the other OHSs, it is impossible to deduce from the released figures whether the respondent worked in terms of a weekly, monthly or annual reporting period.

3.2 The later OHSs: 1997 to 1999

Compared to the earlier period the survey instruments show much fewer changes (see Figure 14). The question that asks for a Rand amount for **employees** is phrased in 1997 and 1998 as :

> What is (the person's) total salary/pay (including overtime and bonus) at the MAIN job (before any deductions)?

In 1999 the question is yet more specific:

> What is ......'s total salary/pay at the main job? Including, overtime, allowances and bonus, before any tax or deductions. Give amount in figures, without any text

As Daniels (2013) notes, the reporting period also shows some changes. In 1997 and 1998 the question allows daily, weekly and monthly amounts, i.e. the annual category has been dropped (compared to 1994 and 1995), while in 1999 the reporting periods are weekly, monthly and annual. He notes that over this period Statistics South Africa introduce new categories of "missing" - besides "unspecified", there now is also "don't know" (introduced in 1999). Furthermore in the 1999 survey it is possible to pinpoint individuals who respond on behalf of others. It transpires that such individuals are much more likely to give bracket information than Rand amounts (Daniels 2013, Table 4, p.27).

The earnings question for **employers or the self-employed** changes in several respects. The questions in 1997 and 1998 were to all intents and purposes identical to the one for 1996, except that provision was made for giving a Rand amount (see Figure 15). The reporting period in this case is weekly, monthly and annual. In 1999, however, the question asks about "total income" only, dropping all references to "turnover". Concomitantly the question about expenses incurred in obtaining the income was dropped (see Figure 16). Clearly the intention is that business deductions (raw materials and salaries of employees) should be netted out. Of course many self-employed would not be affected by this. Furthermore the earnings brackets now correspond to those for employees, i.e. the top two categories of the "self-employed" scale get lost.

What is the impact of these changes? In 1997 and 1998 it is possible to calculate both the "gross turnover" figure and the residual (i.e. "earnings") after business expenses have been deducted. One big difference is that in around 16% cases in 1997 and 14% in 1998 the deductions exceed the gross turnover figure[1], resulting in negative earnings. From 1999 onwards the earnings question presupposes that only nonnegative earnings are possible[2]. This raises the question what to do with the negative values in earlier years. We have chosen to set them to missing. Figure 2 shows the impact of the expenses on the cumulative distributions of self-employment earnings in 1997 and 1998. It is evident that correcting for expenses makes a difference. It is also noticeable that the distribution function for 1998 is well to the left of that for 1997. Part of the reason for this is that after 1997 the surveys were progressively more successful in finding small scale "informal" activities, significantly lengthening of the left tail of the distribution of self-employment earnings.

Figure 3 looks at the self-employment distributions for 1997, 1998 and 1999 (after deducting business expenses) for those reporting earnings above R2500 per month. The shift in the question between 1998 and 1999 does not seem to have affected the distribution.

3.3 The LFSs: 2000 to 2007

As noted above, the Labour Force Surveys no longer distinguish between those working for themselves (employers/self-employed) and those working for others in the earnings question.

---

[1] This is after correcting the expenses given by annual paid workers down, for reasons discussed below.

[2] This raises the interesting question why negative earnings should be ruled out *a priori* given that some entrepreneurs do go bankrupt.
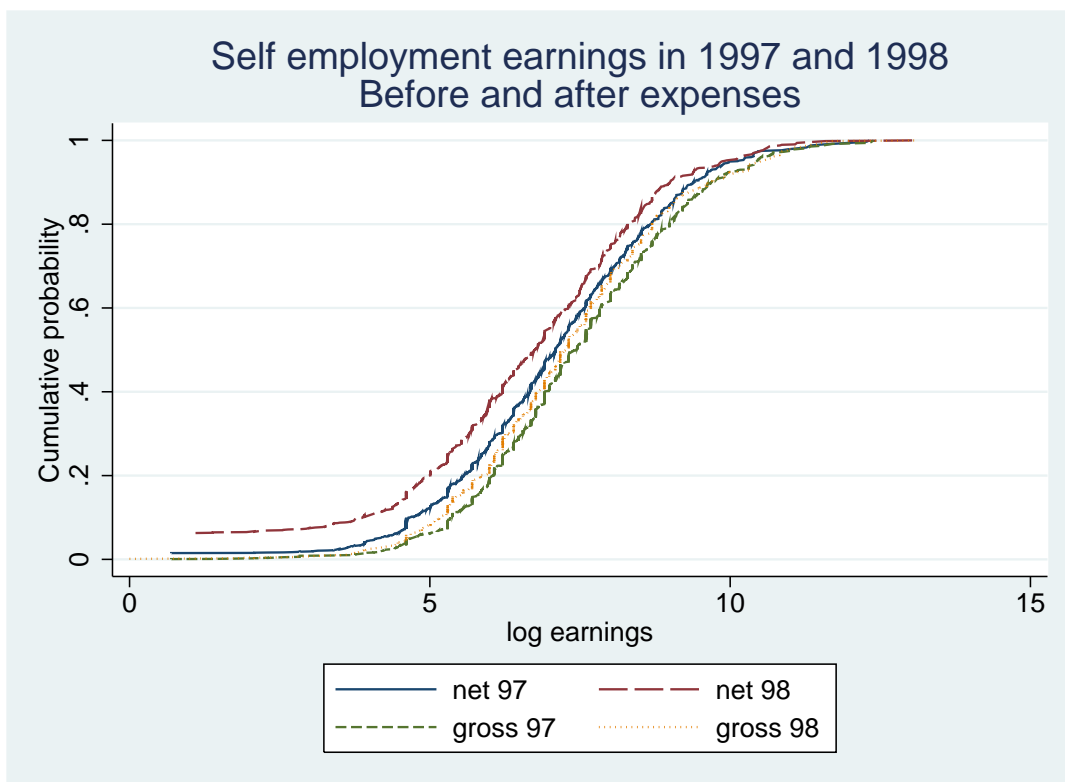

Figure 2: The expenses make a noticeable difference to the cumulative distributions

Figure 3: Cumulative distributions for people reporting nominal self-employment earnings above R2500 per month. Business expenses have been deducted in the case of the 1997 and 1998 datasets.

Table 3: Earnings Information by Survey

Survey	Wage Informa-tion	Self-employment Income	Both	Total
OHS 1994	29,689	5,508	299	35,496
	83.64	15.52	0.84	100
OHS 1995	26,662	4,675	298	31,635
	84.28	14.78	0.94	100
OHS 1996	12,887	1,031	206	14,124
	91.24	7.3	1.46	100
OHS 1997	23,397	2,411	62	25,870
	90.44	9.32	0.24	100
OHS 1998	14,647	1,611	136	16,394
	89.34	9.83	0.83	100
OHS 1999	20,042	3,054	229	23,325
	85.92	13.09	0.98	100
Total	127,324	18,290	1,230	146,844
	86.71	12.46	0.84	100

Raw frequencies and row percentages are shown in the table

The earnings question (see Figure 17) looks very similar to the OHS 1999 question for employees and indeed comparable to the 1999 OHS question for the self-employed, except that the reference is now to income from the **main job** instead of from all own account business activities. One additional implication of this change is that it becomes impossible to answer both questions. In the previous OHSs there were always a handful of individuals who gave information (whether categorical or value) on both, as shown in Table 3.

3.4 The QLFSs: 2008 onwards

With the introduction of the QLFS, the earnings question was initially dropped. The reason for this was criticism from an IMF delegation that assessed labour market statistics. Their objection (cited in Statistics South Africa's official response) was that

> Data on earnings are collected each survey but considered to be poor quality, especially for the self-employed. Question has relatively high refusal/non-completion rates. Data are not published; hence the importance of the data is not appreciated by the survey officers. (Statistics South Africa 2008, Section 2.3.5, pp.7-8)

The earnings question reappeared in the third quarter of 2009, although the data from 2009 have not been released. The QLFS earnings module shows a reversion to two questions, one for employees and one for employers and own account workers (see Figures 18 and 19 respectively). The same set of brackets were used for both (see Figure 20). Unlike the OHSs, it was impossible to give both a wage and a self-employment income, because there was a prior screening question (Question 5.1) which categorised individuals as either working for someone else or as an employer or own-account worker. Another difference with respect to both the OHS and LFS is that the reporting period now includes the possibility of being paid fortnightly or hourly.

One additional point to note is that the QLFS with earnings information was released separately, under the label of "Labour Market Dynamics in South Africa" study.

4 Analysing the Response Patterns

While changes in the instrument are an obvious source of differences between surveys, there are a number of other important factors. The first of these is changes in coverage, both for the survey as a whole and which people ended up answering the earnings question. The second is field work practice, i.e. the extent to which fieldworkers probed or were able to elicit good responses. The third is respondent behaviour. Fourth is post-fieldwork data processing. In practice very little of how these processes were implemented or changed over time is documented. Much of it has to be deduced from the response patterns observable in the data itself.

4.1 Changes in Coverage

There are several important "breaks" in the coverage of the earnings question. It is well-known that the earliest OHSs did not cover mining employment well. This will obviously impact on the representation of low earning categories of work. Kerr and Wittenberg (2013) argue that the OHSs up to 1998 significantly underenumerated backyard shacks and small households. This led to the underenumeration of certain categories of employed people, probably disproportionately low earners (such as domestic workers).

With the introduction of the LFSs, there was a much greater emphasis on capturing informal activities, including subsistence agriculture (see Figure 4). The coverage of those classified as "employed" therefore increased substantially. Since many of these were low earners, this will have an appreciable impact on the measured earnings distribution. With the introduction of the QLFSs the subsistence agriculture sector seems to disappear again.

There are several more idiosyncratic changes in coverage. The February 2001 LFS shows a much higher level of informal activity than any other survey in the 1994-2011 period. The reason is that the LFS served as screener survey for the Survey of Employers and the Self-employed (SESE). Fieldworkers were apparently paid on a piece-work basis (personal communication, Statistics SA staff) and the SESE questionnaire was administered after the LFS one. They therefore had a direct pecuniary interest in finding as much informal activity as possible.

Less explicable is the spike in subsistence agricultural production in the February and September 2000 LFS (see Yu 2007, Table 14,p.19). This may be due to changed fieldwork instructions, as speculated by Charles Meth (personal communication).

4.2 Brackets and Point Responses

Tables 9, 10 and 11 present the proportion of individuals giving point information (actual Rand amounts) within each of the surveys and separated by employees and the self-employed. Within each survey the probability of giving precise information declines noticeably with income. Nevertheless there are also clear differences between surveys. The response rate jumps between OHS 1999 and the LFSs, suggesting that enumerators were more successful in eliciting precise information, perhaps due to changed enumerator training, fieldwork instructions or fieldwork control. The QLFSs have no "brackets only" responses, indicating that Statistics South Africa imputed Rand amounts for these responses.

4.3 Changes in data cleaning practices

The 1994 data earnings data include imputations for brackets as well as conversion of all figures to a net monthly income figure. The imputation process seems to have been a variant of mean imputation, resulting in significant "spiking" in the distribution as shown in 5. Wittenberg
Figure 4: Measured self-employment jumps with the introduction of the LFS. The jump is particularly pronouned in agriculture.
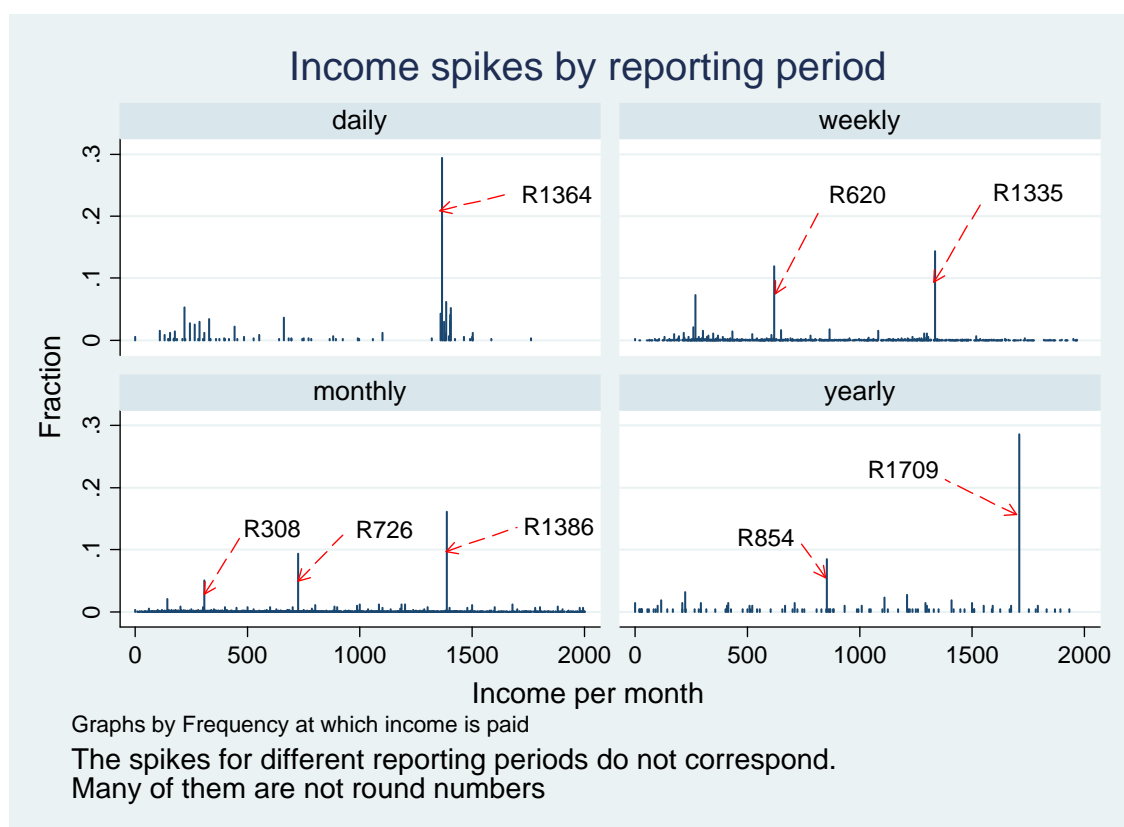

Figure 5: The imputation process in the 1994 OHS led to significant spiking of reported earnings at strange numbers (Wittenberg 2008a, Figure 1)

(2008a) tries to reconstruct in some detail the "spike generating process" in order to separate out genuine point information from bracket responses.

The imputations in the QLFS do not lead to similar spikes, probably because some variant of a hot deck was employed. Nevertheless hot decks can also induce more limited forms of heaping, if the same value is copied to several other observations. Arguably this is what might have happened in the 2011 Q2 version of the QLFS, where the 14 largest monthly earnings figures among the self-employed are R 250 000 (4 observations), R 333 666 (2 cases), R 600 000 (2 times) and R 1 000 000 (6 individuals). The clumping of the millionaires is sufficient to increase the mean income by around R 2 000 in that quarter.

There are other forms of data cleaning that have changed over time. In 1997 everyone who has any form of earnings information is placed into a bracket. This suggests some post-fieldwork imputation since the questionnaire is clear that the categories should be shown only if the respondent refuses to give a Rand amount. Interestingly in both 1997 and 1998 there are many cases where the point information contradicts the bracket (see below). By 1999 this hardly occurs at all.

Table 4: Mismatch between Rand and bracket information in the 1997 OHS

Actual	Recorded bracket information											
	0	1	2	3	4	5	6	7	8	9	10	11
1	0	49	0	0	0	0	0	0	0	0	0	0
2	1	25	1,591	757	1,086	85	52	12	13	2	2	1
3	2	28	130	2,786	208	832	696	22	7	14	6	3
4	3	15	60	49	2,875	76	64	194	48	11	7	7
5	2	4	46	29	26	2,755	142	5	9	27	21	1
6	0	5	44	35	17	60	3,181	136	7	4	9	17
7	2	0	11	37	1	6	34	1,751	68	5	0	0

Actual brackets were constructed from actual Rand amounts, where given, and
bracket responses otherwise. Only a subset of the full cross-tabulation is shown.

Table 5: Missing earnings information by survey

Survey	fraction	Survey	fraction
OHS 1994	0.002	LFS 04:2	0.069
OHS 1995	0.014	LFS 05:1	0.058
OHS 1996	0.052	LFS 05:2	0.056
OHS 1997	0.048	LFS 06:1	0.037
OHS 1998	0	LFS 06:2	0.046
OHS 1999	0.079	LFS 07:1	0.041
LFS 00:1	0.090	LFS 07:2	0.049
LFS 00:2	0.038	QLFS 2010:1	0.003
LFS 01:1	0.051	QLFS 2010:2	0.002
LFS 01:2	0.061	QLFS 2010:3	0.002
LFS 02:1	0.061	QLFS 2010:4	0.002
LFS 02:2	0.072	QLFS 2011:1	0.002
LFS 03:1	0.061	QLFS 2011:2	0.002
LFS 03:2	0.079	QLFS 2011:3	0.003
LFS 04:1	0.061	QLFS 2011:4	0.002

4.4 Respondent or fieldworker errors

The mismatch between the Rand information and the brackets is shown in Table 4. It is evident
that there are a lot of off-diagonal elements. Given the wording of the question (see Figure 14)
it is difficult to know how it was possible for respondents to answer both, let alone produce
inconsistent replies. It is evident that there must have been some combination of fieldworker and
respondent error. It raises the issue of how to deal with the conflicting information. We have
chosen to take the actual Rand amount as authoritative, where it is available.

4.5 Missing values

Daniels (2013) has described the increased sophistication in the instrument in dealing with miss-
ing values. There are nonetheless some curious patterns in Table 5. It shows the fraction of
respondents giving one of the "nonresponse" codes released with the data ("don't know", "re-
fused" or "unspecified"), i.e. it excludes the "not applicable" (unemployed or out of the labour
force).

Table 6: Missing earnings information in the LFSs by category

Survey	valid	DK	refused	unspecified
LFS 00:1	0.910	0.042	0.027	0.021
LFS 00:2	0.962	0.004	0.008	0.026

LFS 02:2	0.928	0.032	0.037	0.003
LFS 03:1	0.939	0.023	0.036	0.002
LFS 03:2	0.921	0.025	0.051	0.002
LFS 04:1	0.939	0.021	0.038	0.003
LFS 04:2	0.931	0.026	0.040	0.004
LFS 05:1	0.942	0.018	0.036	0.004
LFS 05:2	0.944	0.019	0.034	0.003
LFS 06:1	0.963	0.009	0.026	0.002
LFS 06:2	0.954	0.013	0.030	0.003
LFS 07:1	0.959	0.012	0.024	0.004
LFS 07:2	0.951	0.014	0.028	0.007

A startling figure is the zero for 1998. It doesn't mean that there were no refusals – just that they were not recorded as such in the dataset. It is also seems clear that refusals in the QLFS data have been replaced by imputed values. Table 6 provides a more detailed look at the LFS cases. As Daniels (2013) has argued the measurement instrument had stabilised in this period, so changes between surveys are due either to "real" changes (respondent behaviour) or changes in fieldwork or data cleaning practice. The marked reduction in the proportion of "unspecified" responses is most likely a sign of better fieldwork and fieldwork control. Indeed it is difficult to fathom what an "unspecified" response could be given the availability of the other nonresponse codes. The steady reduction in "don't know" and "refused" answers also suggests more stringent fieldwork control. The case of the September 2000 LFS, with hardly any of these responses looks clearly anomalous.

4.6 Zero Earnings

Vermaak (2012) has argued that how one deals with individuals recording zero income can markedly affect one's analysis, particularly if one is investigating the "working poor". There are several mechanisms that might lead to a zero being recorded:

- The worker earns a positive income, but wants to signal that it is a pittance.

- The individual is self-employed and is not valuing consumption from own production or from inventories (in the case of traders). Zero surplus at the end of the period is equated with zero income.

- The individual works in a family enterprise and is not factoring in that they are receiving income in kind.

- The individual is self-employed and in fact made a loss, but can't report this.

- The individual is working as a volunteer (e.g. to gain experience)

- The individual is working on some deferrred compensation scheme. Own-account agriculture which may yield income only at harvest time may be an example of this also.

The majority of these cases are species of measurement error. They are also cases where it is somewhat doubtful whether the "data generating process" is directly comparable to those of individuals reporting positive earnings. Table 7 suggests that zero earners are a big issue only in the LFSs, and then only among the self-employed. Given that the LFSs are marked by a big increase in subsistence agricultural workers, it suggests that the high proportion of zero earners in the LFSs is an artefact of the change in coverage. This is demonstrated in the last column of Table 7 where we show that more than 90% of zero earners in the LFSs come from the agricultural sector. Consequently we have made no attempt to correct for zero earnings.

4.7 Outliers

While zero earners may influence the poverty rates, extremely large values have the potential to shift the mean, as argued by Burger and Yu (2007). Table 8 confirms their point that "millionaires" (in year 2000 Rands) are not evenly distributed over the surveys. The 1999 October Household Survey and the September 2000 Labour Force Survey look clearly anomalous within the OHS and LFS sequence. There also looks to be a break between the LFSs and the QLFSs. Indeed the QLFSs seem to show a markedly higher count of millionaires, induced, perhaps, by the imputation of missing information alluded to in section 4.3. Some of the most extreme values were recorded in the QLFSs – and they tend to occur in clumps. In the third quarter of 2010, for instance, there were three self-employed individuals recording an income of precisely R10 million (nominal) *per month*[3].

The presence or absence of such extreme values has a marked influence on average incomes in those surveys. It is therefore desirable to remove their influence. Three approaches were considered:

1. *Remove the "millionaires"*

   This was the approach taken by Burger and Yu (2007). This obviously lops off the top tail and risks removing "genuine millionaires" along with any bogus ones. It is also rather arbitrary in that there may be bogus observations at lower levels of income.

2. *Outlier detection*

   There are a number of outlier detection algorithms available (see (Billor, Hadi and Velleman 2000) for a review). The BACON algorithm (Billor et al. 2000) has been implemented as a Stata routine (Weber 2010) and was used here for that purpose. The basic problem of every outlier detection algorithm is that the presence of the outliers can contaminate any statistics calculated to detect those outliers. The BACON algorithm begins with a small subset of observations assumed safe from contamination and then incrementally adds (in blocks) observations that are "close" to the existing safe set. The distance measure used is the Mahalanobis distance $\sqrt{(\mathbf{x}_i - \overline{\mathbf{x}})' \mathbf{S}^{-1} (\mathbf{x}_i - \overline{\mathbf{x}})}$ where $\overline{\mathbf{x}}$ and $\mathbf{S}$ are the mean and covariance matrix calculated on the "safe" set and $\mathbf{x}_i$ is the vector under consideration. One of the drawbacks of this procedure is that it works better on continuous data. Most of the covariates available are discrete and this blunts the ability of the procedure to find

---

[3]The three highest values recorded in the dataset are all in the first quarter of 2011, viz. 86 million, 68 million and 60 million (per month). Since these all fall outside the "valid range" noted in the metadata, they are undoubtedly bad data.

Notes:

Millionaires defined by annual earnings in year 2000 Rands

Proportion based on sample giving Rand information.

Population total estimate includes bracket correction.

anomalous data. It should be noted that these distance measures work better also with symmetrically distributed data, so the earnings data was logged before applying the routine.

The BACON algorithm found only five clearly anomalous observations when using education categories as covariates. The flagged outliers were, indeed, all anomalous – including the three bad data points referred to in footnote 3.

3. *Extreme regression residuals*

The BACON algorithm treats all variables used to locate outliers symmetrically. Economists tend to think of earnings as the outcome in which education and, perhaps, occupation, are the explanatory variables. Consequently a Mincerian style regression was run with survey specific intercepts, gender, race (both interacted with survey), a quadratic in age, education categories and occupation categories as explanatory variables. One issue that has to be addressed when trying to identify "extreme" residuals, is that points of high leverage will tend to be associated with smaller residuals. The "Studentised residual" corrects for that. It is defined as

$$r_i = \frac{e_i}{\sqrt{s_{(i)}^2 \left(1 - h_i\right)}}$$

where e_i is the "unstandardised" residual, $s_{(i)}^2$ is an estimate of the residual variance with the i-th observation removed and h_i is the leverage (StataCorp 2013a, "regress postestimation" p.1877).

"Studentized residuals can be interpreted as the t statistic for testing the significance of a dummy variable equal to 1 in the observation in question and 0 elsewhere (Belsley, Kuh, and Welsch 1980). Such a dummy variable would effectively absorb the observation and so remove its influence in determining the other coefficients in the model." (StataCorp 2013a, p.1877)

Studentised residuals with absolute values greater than five were flagged as extreme. The probability of being flagged if the underlying population is well-behaved is $5.735*10^{-7}$. On a sample of around 500 000, one would expect on average to see 0.3 observations this extreme. In practice the procedure flagged 476 observations, including a number deemed to be implausibly low.

4. *Robust regression*

One problem with using the "Studentised residual" approach is that the presence of a group of outliers will again contaminate the data, making it harder to identify the bad observations. Robust regression attempts to deal with this issue recursively: progressively downweighting observations that appear to be problematic until the regression results and the weights are in agreement. Running this procedure led to over 1000 observations being weighted right down to zero. Every one of the "extreme" values identified through the Studentised residuals was also identified as problematic by the robust regression.

In order to be not overly aggressive in removing high values we opted to use the third approach as the preferred approach for dealing with outliers.

5 Ways of dealing with Coarse Data

Given the fact that the probability of providing bracket-only information increases with income (see Section 4.2) one has to deal explicitly with the bracket responses in order to obtain unbiased estimates. There are many ways in which this can be done.

5.1   Deterministic imputation

The most common procedure (discussed, for instance, by von Fintel (2007)) is to place individuals at either the midpoint or the mean of the observations within the bracket. In the case of the "open" category there is no midpoint, so the procedure is to place observations at some deterministic multiple of the lower bracket boundary, as discussed earlier. Both approaches will lead to artificial spikes in the data and will definitely distort moments other than the mean. They also do not acknowledge that the imputed value is actually the true value with some noise.

5.2   Reweighting

A simple alternative to imputation is to reweight the point information to take into consideration the bracket responses (Wittenberg 2008b). Numerically it will provide identical results to the imputation of means, but it has the advantage of not altering any of the other moments. Among the disadvantages of this approach is that it cannot be used when there is no point information within a bracket and it tends to inflate the standard errors, since the approach only fully counts observations with actual Rand amounts.

5.3   Stochastic Imputation

One way of avoiding putting all imputed values at the same number (e.g. midpoint or mean) is to draw the imputed value from some random distribution, effectively adding some noise to the imputed value. There are again different ways in which this can be done.

5.3.1   Parametric

A distribution can be specified beforehand and the draw taken from there. Woolard and Woolard (2006), for instance, used a uniform distribution within a bracket. Alternatively one could take draws from a truncated log-normal[4]. Obviously the distribution chosen will have an influence on where the observations are placed within the brackets and hence will affect statistics calculated with those values.

5.3.2   Posterior distribution

An additional problem with taking a draw from a distribution whose parameters have been empirically estimated (e.g. the truncated log-normal) is that the process does not acknowledge the uncertainty implicit in the estimation process. One can address this by first taking a draw from the posterior distribution of the estimators (e.g. draw a σ_*^2 from the chi-square distribution[5] and then draw μ_* from a normal distribution centred on $\widehat{\mu}$ with variance $\frac{\sigma_*^2}{n-1}$). The actual imputation would then be drawn from the distribution defined by the parameter μ_* and σ_*^2.

---

[4]This would require estimating the parameters of the distribution, which could be done using a maximum likelihood approach.

[5]with a non-informative prior we have that

$$\frac{\widehat{\sigma}^2\,(n-1)}{\sigma^2} \sim \chi_1^2$$

So the posterior distribution of σ^2 will be given by

$$\frac{\widehat{\sigma}^2\,(n-1)}{\chi_1^2}.$$

5.3.3 Hot deck

In the case of hot decks, the draw is from the empirical distribution, in this case observations falling into the same bracket. There are different flavours: "deterministic" ones in which the "nearest neighbour" is drawn according to some criterion (typically involving a number of covariates) and more "random" ones in which one value is picked out of a pool (for a fuller discussion see Andridge and Little 2010). The advantage of the hot deck (like reweighting) is that only data that are empirically observed will be utilised. In cases where the "donor pool" is small, it can lead to the same value being copied to a number of other observations.

5.3.4 Predictive mean matching

The key issue for a hot deck is how the "distance measure" is defined. The problem is that the variables on which the "pool" is based need to be correlated with the outcome to be imputed but also related to the nonresponse mechanism. An attractive option is to regress the outcome (in this case earnings) on the available covariates (in this case dummies for earnings brackets, gender, education, and whether it was an employee or somebody self-employed). Distance is then measured by the distance between the predicted outcomes (which is defined even for indiviuals missing the dependent variable). Of course this again treats the estimates as fixed, so it is preferable to take the draw from the posterior distribution of predicted outcomes.

5.4 Multiple imputations

One of the big problems with stochastic imputation is that the resulting value does not signal any of the uncertainties implicit in the process of producing the imputation. The resulting value will be the true value plus some measurement error, but the error has been rendered invisible. The theoretical solution for this problem is to do the imputation multiple times and perform any statistical analyses (e.g. calculation of summary statistics) on all of the resulting datasets (Rubin 1987, StataCorp 2013b). By taking into consideration the differences in estimates between analyses one can obtain appropriate point estimates and standard errors.

5.5 Maximum Likelihood

There are situations in which one can sidestep the issue of imputation altogether. If one is willing to assume a parametric form for the statistical process it is possible to accommodate both coarsened data and the point information within the overall likelihood function. "Interval regression" and "censored regression" models are examples of these, but the approach can be used more generally. These approaches make strong assumptions which may not be all that attractive if there is any doubt about the applicability of the assumed distribution

6 Dealing with Missing Information

All of the approaches outlined in the case of coarsened data can also be used if the data is missing altogether. The "reweighting" approach fails if there are no actual observations to reweight. The 1996 OHS survey records information only in brackets and so the reweighting approach is not really applicable. Instead we took multiple draws from the 1997 real earnings distribution, using predictive mean matching, taking the 1996 covariates into account.

In cases where the bracket information was missing, we (multiply) imputed brackets using an ordered logit model with province, gender, education, race, a quadratic in age and occupation

as explanatory variables. The imputed brackets were then (along with gender and education) to multiply impute Rand amounts, using predictive mean matching.

7 Harmonising the sample weights

One final issue needs to be addressed if one is to obtain a consistent set of estimates over time: the harmonisation of the sample weights released with each survey. Branson and Wittenberg (forthcoming) have argued that there are also breaks in the way in which survey weights were constructed and that this can lead to jumps in a series which are unrelated to "real" changes. The weights that have been released with the PALMS 2 dataset have all been calibrated to the ASSA 2008 demographic model.

8 The impact of data quality adjustments on average real earnings

Figure 6 shows the impact of different types of data quality adjustments on the estimation of average earnings over the period 1994 to 2011. The dotted line indicates that outliers would have moved the mean up substantially in both 1999 and September 2000. The gap between the green dashed line and the other lines indicates the importance of taking appropriate account of the bracket information. It is evident that the multiply imputed sequence (indicated as "imputed" in the figure) produces a slightly higher income than the other two approaches, mainly because it also imputes for observations which were completely missing.

Interestingly the pattern suggested in this Figure does not suggest that there were dramatic movements downwards in average wages. The "dip" at the point at which the LFSs were introduced can be explained in terms of changes in coverage. Overall the picture suggests real earnings growth since 2000. In the period of the QLFSs there are no discernible differences between the series anymore, because missing information and brackets have already been imputed for.

Figure 7 presents the analogous graph in the case of the self-employed. We do not show the line with outliers, since the spikes are so huge that no changes can be discerned in any of the other parts of the graph. Again we observe the importance of dealing with brackets. We again observe that imputing for the missings raises average earnings a bit. In this case we see a big shift in mean earnings precisely at the point where the LFS was introduced. This coincides with the big change in coverage noted in Figure 4. Again the period since 2000 seems to show growth in average real earnings. The curious spike in the QLFS period is due to the clump of "millionaires" referred to earlier. These values were not removed by the outlier detection algorithm and hence the spike appears in the picture.

9 Conclusion

Given the changes documented in this paper one might be inclined to despair of being able to say anything meaningful about the evolution of earnings since 1994. We believe, however, that it is possible to discern some meaningful trends through the noise generated by these measurement changes. Any attempt to grapple with South African labour trends in the post-Apartheid period will at some stage confront the issue of dealing with earnings data. We hope that the PALMS 2 dataset will contribute to a debate that isn't derailed by "dirty" data.

3.27 How many people are/were working for...... (including unpaid and family workers) during the last month that he/she worked?	
Number of employees: **Unpaid**	
Paid	

Figure 16: The earnings question for the self-employed/employers in the 1999 OHS.

	01
4.15.a What is ……'s total salary/pay at his/her <u>main</u> job? *Including overtime, allowances and bonus, before any tax or deductions.* *Give amount in whole figures, without any text or decimals* *If refusal or don't know* → ***Go to Q 4.15.c***	

Only if amount given in 4.15.a
 4.15.b Is this
     1 = Per week
     2 = Per month
     3 = Annually
	☐ 1
	 ☐ 2
	 ☐ 3

Only if refusal or don't know in 4.15.a

4.15.c Show the categories. Make sure the respondent points at the **correct income column** (weekly, monthly, annually) on **Show card 3** and mark the applicable code.

About DataFirst

DataFirst is a research unit at the University of Cape Town engaged in promoting the long term preservation and reuse of data from African Socioeconomic surveys.

This includes:

the development and use of appropriate software for data curation to support the use of data for purposes beyond those of initial survey projects,
liaison with data producers - governments and research institutions - for the provision of data for reanalysis,
research to improve the quality of African survey data,
training of African data managers for better data curation on the continent,
training of data users to advance quantitative skills in the region.

The above strategies support a well-resourced research-policy interface in South Africa, where data reuse by policy analysts in academia serves to refine inputs to government planning.
